Abstract

- Background. An increasing body of literature suggests that there is a crucial role for the microbiota in colorectal cancer (CRC) pathogenesis. Important drivers within this context have ranged from individual microbes to the whole community. Our study expands on a recent meta-analysis investigating microbial biomarkers for CRC by testing the hypothesis that the bacterial community is an important driver of both early (adenoma) and late (carcinoma) stage of disease. To test this hypothesis we examined both feces (n = 1737) and tissue (492 total samples from 350 individuals) across 14 different studies.
- Results. Fecal samples had a significant decrease from control to adenoma to carcinoma for both Shannon diversity and evenness (P-value < 0.05) after correcting for study effect and variable region sequenced. Only evenness for adenoma (P-value < 0.05) resulted in a slightly increased relative risk while lower Shannon diversity and evenness in fecal samples resulted in a significant increase in relative risk for carcinoma (P-value < 0.05). Previously associated colorectal cancer genera (Fusobacterium, Parvimonas, Peptostreptococcus, or *Porphyromonas*) followed a similar pattern with a significantly increased relative risk by their presence for carcinoma (P-value < 0.05) but not adenoma (P-value > 0.05) with 16 the exception of *Porphyromonas* (P-value < 0.05). Using the whole community versus only CRC associated genera to build a prediction model resulted in higher classification 18 success based on Area Under the Curve (AUC) for both adenoma and carcinoma using fecal and tissue samples. For the included studies, most were adequately powered for large effect size differences. This may be more amenable for carcinoma than for adenoma microbiota research due to the smaller community level changes observed in our results.
- Conclusions. This data provides support for the importance of the bacteral community to both adenoma and carcinoma genesis. The evidence collected within this study on the role of the microbiota in CRC pathogenesis is much stronger for carcinoma then adenoma.

- ²⁶ A strong reason for this may be in part due to the low power to detect more subtle changes
- 27 in the majority of studies that have been performed to date.

28 Keywords

microbiota; colorectal cancer; polyps; adenoma; meta-analysis.

30 Background

Colorectal cancer (CRC) is a growing world-wide health problem [1] in which the microbiota has been purported to play an active role in disease pathogenesis [2]. Numerous studies have shown the importance of both individual microbes [3–7] and the overall community [8–10] in polyp formation using mouse models of CRC. There have also been numerous case/control studies investigating the microbiota in the formation of both adenoma and carcinoma. Recently, a meta-analysis was published investigating whether specific biomarkers could be consistently identified using multiple data sets [11]. Many of the studies, along with the previous meta-analysis, focus on identifying biomarkers or individual microbes but do not critically investigate the role the community has in CRC.

Using both feces (n = 1737) and tissue (492 samples from 350 individuals) totalling over 2229 total samples across 14 studies [12–25] [Table 1 & 2], we expand both the breadth and scope of the previous meta-analysis to investigate whether the bacterial community is an important risk factor for both adenoma and carcinoma. To accomplish this we first assessed whether the diversity changes throughout disease (control to adenoma to carcinoma) and if it results in an increased relative risk (RR) for adenoma or carcinoma. Next, we assessed how common CRC-associated genera (*Fusobacterium*, *Parvimonas*, *Peptostreptococcus*, or *Porphyromonas*) affect the relative risk of adenoma or carcinoma. Third, using Random Forest models, we analyzed whether the full community or only the CRC associated genera resulted in better model classification based on the area under the curve (AUC). Since the changes in community were subtle for adenoma we also examined what effect and sample size the studies that were used were adequately powered for.

Our analysis found a continuous decrease in Shannon diversity as disease became more severe which correlated with a significantly increased RR for carcinoma. Using only CRC-associated genera, the RR for carcinoma was higher relative to what was observed for the Shannon diversity RR. Conversely, we demonstrate that the AUC of the classification models increased when the full community was incorporated as opposed to only CRC-associated genera. Although we analyzed data sets which sampled large numbers of individuals, our results indicate the individual studies were underpowered for detecting effect size differences of 10% or below between the case and control groups.

Results

Lower Community Diversity is Associated with Increased RR of Carcinomas: Using power transformed and Z-score normalized α -diversity metrics, both evenness and Shannon diversity in feces, but not tissue, were lower in those with carcinoma [Figure 1]. Using linear mixed-effect models to control for study and variable region, there was a significant decrease from control to adenoma to carcinoma for both evenness (P-value = 0.025) and Shannon diversity (P-value = 0.043). However, in tissue, this effect was not observed in tissue when resampling of the same individual was also controlled for (P-value > 0.05). Within fecal samples, a decrease in Shannon diversity and evenness resulted in a significantly increased RR for carcinoma (P-value = 0.01 and 0.0011, respectively) [Figure 2]. Although these values were significant, the effect size was relatively small for both metrics (Shannon RR = 1.31 and evenness RR = 1.34) [Figure 2]. Only a decrease in evenness had an increased RR for adenoma (P-value = 0.032) [Figure 2A & S1] but this effect size was even smaller than what was observed for carcinoma (RR = 1.16).

Using the Bray-Curtis distance metric, there was a significant difference across studies in the bacterial community of fecal samples between carcinoma and controls, but not adenoma and controls [Table S1 & S2]. For studies with unmatched tissue samples a similar trend was observed [Table S3 & S4] while studies with tissue samples from the same individual (matched) had no differences [Table S3 & S4].

CRC-associated Genera Minimally Impacts RR of Adenoma: The majority of CRC-associated genera for both feces and tissue had a significantly increased RR for carcinoma but not for adenoma [Figure 3]. In fecal samples the RR due to CRC associated genera was greater than either the RR assoicated with evenness or Shannon diversity [Figure 2 & 3]. Additionally, the RR of carcinoma continuously increased as individuals tested positive for more CRC associated genera [Figure 3B & 3D]. The RR effect size was

greater for stool (RR range = 1.61 - 2.74) than for tissue (RR range = 1.21 - 1.81). This
decrease may be explained by the fact that the tissue analysis included matched samples
from the same individual.

There were two significant measures for increased RR of adenoma when investigating CRC-associated genera in stool: 1) Having a higher then median value of *Porphyromonas* (P-value = 0.023) and 2) whether samples were positive for three CRC associated genera (P-value = 0.022) [Figure 3A]. With tissue, there were three significant measures for an increased RR of adenoma: 1) being positive for one CRC-associated genera (P-value = 0.032), 2) being positive for two CRC associated genera (P-value = 0.008), and 3) being positive for four CRC associated genera (P-value = 0.039) [Figure 3C].

Using the Whole Community Instead of Only CRC-Associated Genera Increases
 Model AUC: For both fecal and tissue (matched and unmatched) samples, the AUC decreases when only OTUs from the CRC-associated genera are used [Figure 4 & 5]. This decrease is observed in both adenoma and carcinoma groups [Figure 4 & 5]. The genus models generally performed similar to the OTU-based models with the full genera models performing better than the CRC-associated genera models [Figure S2-S3]. Both genus models were similarly predictive in their ability to detect adenomas or carcinomas, with carcinoma having a higher AUC then adenoma [Figure S4-S5]. Of note, matched tissue samples for those with carcinoma had an AUC that was more similar to the adenoma models [Figure S4A, S5B, & S6] than carcinoma models [Figure S4B & S5A].

A Majority of Studies are Underpowered for Detecting Small Effect Size Differences:

105

When assessing the power of each study at different effect sizes the majority of studies for both adenoma and carcinoma have an 80% power to detect a 30% difference [Figure 6A & B]. No single study that was analyzed had the standard 80% power to detect an effect size difference that was equal to or below 10% [Figure 6A & B]. In order to achieve adequate power for small effect sizes, studies would need to recruit over 1000 individuals for each

arm [Figure 6C].

112 Discussion

Our study identifies clear differences in diversity both at the community level and within individual genera that are present in individuals with CRC versus those without the disease [Figure 1-3]. Although there was a step-wise decrease in diversity from control to 115 adenoma to carcinoma, this did not translate into large effect sizes for the relative risk of 116 either of these two conditions. Even though CRC-associated genera increase the RR of 117 carcinoma, they do not consistently increase the relative risk of adenoma. This information 118 suggests that these specific genera are important in carcinoma genesis but may not be the 119 primary members of the microbial community contributing to the formation of an adenoma. 120 Additionally, our data show that by using the whole community, our models perform better 121 than when only the CRC-associated genera are included. CRC-associated genera are 122 clearly important to carcinoma pathogenesis but accounting for the community in which 123 these microbes exist can drastically increase the ability of models to make predictions. 124 These observations suggest that small localized changes within the community on tissue may be occurring that are important in early disease progression of CRC and that this process may not directly involve CRC-associated genera. 127

The data presented herein supports the driver-passenger model of the microbial role 128 in CRC, as summarized by Flynn [2], when applied to carcinoma but not necessarily 129 adenoma. Both the drastically increased RR of CRC-associated genera versus diversity 130 for carcinoma and increasing RR with more CRC-associated generea positivity are highly 131 supportive of this model. It is also possible that in a driver-passenger scenario, simply 132 having the driver present or only identifying the passenger is a good enough proxy that the 133 event is occurring. This would account for the observation that there is no constant additive 134 effect on RR for increasing positivity. Additionally, the initial establishment of the driver 135 within the system appears to be dependent on the current community. This is supported by our finding that when adding the community context to our models in addition to the CRC-associated genera, the model AUC increases.

154

155

160

161

162

With regards to carcinoma, our results support the driver-passenger model within the 139 framework of the transition from adenoma to carcinoma. Conversely, using the present 140 data, we can only theorize observations related to adenoma development fit this model. 141 The changes that occur at this timepoint are small and possibly focal to the adenoma itself. 142 The stepwise decrease in diversity suggests that the adenoma community is not normal 143 but has changed subtly. Although there appears to be localized changes that do depend on the driver-passenger model, as supported by an increased RR for one, two, and four positive CRC-associated genera in tissue [Figure 3C], there may be other processes at play that ultimately exacerbate the condition from a subtle localized change to a change in the global community. The poor performance of the Random Forest models for classifying adenoma based only on the microbiota would suggest that this is the case. It is possible to hypothesize that at early stages of the diease, the host interacts with these subtle changes 150 and catalyzes what ultimately leads to a thoroughly dysfunctional community. 151

Although there are still questions that need to be answered regarding the microbiota and carcinoma, a clearer framework for their relationship is beginning to develop as to how this occurs. From our observations many changes in carcinoma could easily result in effect sizes that are 30% or more between the case and control and most studies analyzed have sufficient power to detect these types of changes [Figure 6]. Conversely, the role of the microbiota in adenoma is less clear and part of the reason this may be is because many studies are not powered effectively to observe the small changes reported here. None of the studies analyzed were properly powered to detect a 10% or lower change between case and controls. This small effect size range may well be the scope in which differences consistently occur in adenoma due to the subtle changes in community that occur between control and adenoma. Future studies investigating adenoma and the microbiota need to take these factors into consideration if we are to work out how the microbiota contributes

to adenoma formation.

65 Conclusion

By aggregating together a large collection of studies from both feces and tissue, we are 166 able to provide evidence in support of the importance of the bacterial community in both 167 adenoma and carcinoma. We are also able to provide support for the driver-passenger 168 model in the context of carcinoma. However, within the context of adenoma, it is less clear 169 that this relationship exists. These observations highlight the importance of power and 170 sample number considerations when undertaking investigations into the microbiota and 171 adenoma due to the subtle changes in the community. Although there are power limitations 172 associated with adenoma, this report highlights the strong influence the microbiota has on CRC development.

75 Methods

Obtaining Data Sets: Studies used for this meta-analysis were identified through the review articles written by Keku, et al. and Vogtmann, et al. [26,27]. Additional studies not 177 mentioned in the reviews were obtained based on the authors' knowledge of the literature. 178 Studies that used tissue or feces as their sample source for 16S rRNA gene sequencing 179 analysis were included. Studies using either 454 or Illumina sequencing technology were 180 included. Only data sets that had sequences available for analysis were included. Some 181 studies did not have publically available sequences or did not have metadata in which the 182 authors were able to share. After these filtering steps, the following studies remained: Ahn, 183 et al. [21], Baxter, et al. [24], Brim, et al. [17], Burns, et al. [22], Chen, et al. [14], Dejea, et 184 al. [19], Flemer, et al. [13], Geng, et al. [25], Hale, et al. [12], Kostic, et al. [28], Lu, et al. 185 [16], Sanapareddy, et al. [20], Wang, et al. [15], Weir, et al. [18], and Zeller, et al. [23]. The 186 Zackular [29] study was not included becasue the 90 individuals analyzed within the study 187 are contained within the larger Baxter study [24]. Additionally, after sequence processing all the case samples for the Kostic study only had 100 sequences remaining and was not used. This left a total of 14 studies for which analysis could be completed. 190

Data Set Breakdown: In total, there were seven studies with only fecal samples (Ahn,
Baxter, Brim, Hale, Wang, Weir, and Zeller), five studies with only tissue samples (Burns,
Dejea, Geng, Lu, Sanapareddy), and two studies with both fecal and tissue samples (Chen
and Flemer). The total number of individuals that were analyzed after sequence processing
for feces was 1737 [Table 1]. The total number of matched and unmatched tissue samples
that were analyzed after sequence processing was 492 [Table 2].

Sequence Processing: For the majority of studies, raw sequences were downloaded from the Sequence Read Archive (SRA) (ftp://ftp-trace.ncbi.nih.gov/sra/sra-instant/reads/
ByStudy/sra/SRP/) and metadata was obtained from the by searching the respective

200 accession number of the study following website: http://www.ncbi.nlm.nih.gov/Traces/study/.
201 Of the studies that did not have sequences and metadata on the SRA, data was obtained
202 from DBGap for one study [21] and for four studies was obtained directly from the authors
203 [12,13,18,20]. Each study was processed using the mothur (v1.39.3) software program
204 [30]. Where possible, quality filtering utilized the default methods used in mothur for either
205 454 or Illumina based sequencing. If it was not possible to use these defaults, the stated
206 quality cut-offs were used instead. Chimeras were identifed and removed using VSEARCH
207 [31] before *de novo* OTU clustering at 97% similarity using the OptiClust algorithm [32]
208 was utilized.

Statistical Analysis: All statistical analysis after sequence processing utilized the R 209 (v3.4.2) software package [33]. For the α -diversity analysis, values were power transformed using the rcompanion (v1.10.1) package [34] and then Z-score normalized using the car (v2.1.5) package [35]. Testing for α -diversity differences utilized linear mixed-effect models created using the lme4 (v1.1.14) package [36] to correct for study and variable region 213 effects in feces and study, variable region, and individual effects in tissue. Relative risk 214 was analyzed using both the epiR (v0.9.87) and metafor (v2.0.0) packages [37,38] by 215 assessing how many with and without disease were above and below the overall median 216 value within the specific study. Relative risk significance testing utilized the chi-squred test. 217 β-diversity differences utilized a Bray-Curtis distance matrix and PERMANOVA executed 218 with the vegan (v2.4.4) package [39]. Random Forest models were built using both the 219 caret (v6.0.77) and randomForest (v4.6.12) packages [40,41]. Differences between the 220 obtained AUC versus a random model AUC was assessed using T-tests. Power analysis 221 and estimations were made using the pwr (v1.2.1) and statmod (v1.4.30) packages [42,43]. 222 All figures were created using both ggplot2 (v2.2.1) and gridExtra (v2.3) packages [44,45]. 223

Study Analysis Overview: α -diversity was first assessed for differences between controls, adenoma, and carcinoma. We analyzed the data using linear mixed-effect models

and relative risk. β -diversity was then assessed for each inidividual study. Next, four specific CRC-associated genera (Fusobacterium, Parvimonas, Peptostreptococcus, and Porphyromonas) were assessed for differences in relative risk. We then built Random Forest models based on all genera or the select CRC-associated genera. The models were trained on one study then tested on the remaining studies for every study. The data 230 was split between feces and tissue samples. Within the tissue groups the data was further divided between samples from the same individual (matched) and those from different 232 individuals (unmatched) tissue samples. Where applicable for each study, predictions for adenoma and carcinoma were tested. This same approach was then applied at the 234 OTU level with the exception that instead of testing on the other studies, a 10-fold cross 235 validation was utilized and 100 different models were created based on random 80/20 splitting of the data to generate a range of expected AUCs. For OTU based models, the CRC associated genera included all OTUs that had a taxonomic classification to 238 Fusobacterium, Parvimonas, Peptostreptococcus, or Porphyromonas. The power of each study was assessed for an effect size ranging from 1% to 30%. An estimated sample n for 240 these effect sizes was also generated based on 80% power.

Reproducible Methods: The code and analysis can be found here https://github.com/ 242 SchlossLab/Sze CRCMetaAnalysis Microbiome 2017. Unless mentioned otherwise, the 243 accession number for the raw sequences for the studies used in this analysis can be found directly in the respective batch file in the GitHub repository or in the original manuscript. 245

Declarations

247 Ethics approval and consent to participate

Ethics approval and informed consent for each of the studies used is mentioned in the respective manuscripts used in this meta-analysis.

250 Consent for publication

Not applicable.

252 Availability of data and material

A detailed and reproducible description of how the data were processed and analyzed for each study can be found at https://github.com/SchlossLab/Sze_CRCMetaAnalysis_
Microbiome_2017. Raw sequences can be downloaded from the SRA in most cases and can be found in the respective study batch file in the GitHub repository or within the original publication. For instances when sequences are not publicly available, they may be accessed by contacting the corresponding authors from whence the data came.

259 Competing Interests

²⁶⁰ All authors declare that they do not have any relevant competing interests to report.

261 Funding

MAS is supported by a Candian Institute of Health Research fellowship and a University of Michigan Postdoctoral Translational Scholar Program grant.

Authors' contributions

All authors helped to design and conceptualize the study. MAS identified and analyzed the data. MAS and PDS interpreted the data. MAS wrote the first draft of the manuscript and both he and PDS reviewed and revised updated versions. All authors approved the final manuscript.

269 Acknowledgements

The authors would like to thank all the study participants who were a part of each of the individual studies utilized. We would also like to thank each of the study authors for making their data available for use. Finally we would like to thank the members of the Schloss lab for valuable feed back and proof reading during the formulation of this manuscript.

Table 1: Total Individuals in each Study Included in the Stool Analysis

Study	Data Stored	16S Region	Control (n)	Adenoma (n)	Carcinoma (n)
Ahn	DBGap	V3-4	148	0	62
Baxter	SRA	V4	172	198	120
Brim	SRA	V1-3	6	6	0
Flemer	Author	V3-4	37	0	43
Hale	Author	V3-5	473	214	17
Wang	SRA	V3	56	0	46
Weir	Author	V4	4	0	7
Zeller	SRA	V4	50	37	41

Table 2: Studies with Tissue Samples Included in the Analysis

Study	Data Stored	16S Region	Control (n)	Adenoma (n)	Carcinoma (n)
Burns	SRA	V5-6	18	0	16
Chen	SRA	V1-V3	9	0	9
Dejea	SRA	V3-5	31	0	32
Flemer	Author	V3-4	103	37	94
Geng	SRA	V1-2	16	0	16
Lu	SRA	V3-4	20	20	0
Sanapareddy	Author	V1-2	38	0	33

- Figure 1: α -Diversity Differences between Control, Adenoma, and Carcinoma Across Sampling Site. A) α -diversity metric differences by group in stool samples. B) α -diversity metric differences by group in unmatched tissue samples. C) α -diversity metric differences by group in matched tissue samples. The dashed line represents a Z-score of 0 or no difference from the median.
- Figure 2: Relative Risk for Adenoma or Carcinoma based on α -Diversity Metrics in Stool. A) α -metric relative risk for adenoma. B) α -metric relative risk for carcinoma. Colors represent the different variable regions used within the respective study.
- Figure 3: CRC-Associated Genera Relative Risk for Adenoma and Carcinoma in

 Stool and Tissue. A) Adenoma relative risk in stool. B) Carcinoma relative risk in stool.

 C) Adenoma relative risk in tissue. D) Carcinoma relative risk in tissue. For all panels the
 relative risk was also compared to whether one, two, three, or four of the CRC-associated
 genera were present.
- Figure 4: OTU Random Forest Model of Stool Across Studies. A) Adenoma random forest model between the full community and CRC-associated genera OTUs only. B)
 Carcinoma random forest model between the full community and CRC-associated genera
 OTUs only. The dotted line represents an AUC of 0.5 and the lines represent the range in which the AUC for the 100 different 80/20 runs fell between. The solid red line represents the median AUC of all the studies for either the full community or CRC-associated genera
 OTUS only model.
- Figure 5: OTU Random Forest Model of Tissue Across Studies. A) Adenoma random forest model between the full community and CRC-associated genera OTUs only. B)
 Carcinoma random forest model between the full community and CRC-associated genera
 OTUs only. The dotted line represents an AUC of 0.5 and the lines represent the range in
 which the AUC for the 100 different 80/20 runs fell between. The solid red line represents

- the median AUC of all the studies for either the full community or CRC-associated genera
 OTUS only model.
- Figure 6: Power and Effect Size Analysis of Studies Included. A) Power based on effect size for studies with adenoma individuals. B) Power based on effect size for studies with carcinoma individuals. C) The estimated sample number needed for each arm of each study to detect aneffect size of 1-30%. The dotted red lines in A) and B) represent a power of 0.8.

- Figure S1: Relative Risk for Adenoma or Carcinoma based on lpha-Diversity Metrics
- in **Tissue.** A) α -metric relative risk for adenoma. B) α -metric relative risk for carcinoma.
- Colors represent the different variable regions used within the respective study.
- Figure S2: Random Forest Genus Model AUC for each Stool Study. A) AUC of adenoma models using all genera or CRC-associated genera only. B) AUC of carcinoma models using all genera or CRC-associated genera only. The black line represents the median within each group.
- Figure S3: Random Forest Genus Model AUC for each Tissue Study. A) AUC of adenoma models using all genera or only CRC-associated genera divided between matched and unmatched tissue. B) AUC of carcinoma models using all genera or CRC-associated genera only. The black line represents the median within each group divided between matched and unmatched tissue.
- Figure S4: Random Forest Prediction Success Using Genera for each Stool Study.

 A) AUC for prediction in adenoma using all genera or CRC associated genera only. B)

 AUC for prediction in carcinoma using all genera or CRC-associated genera only. The

 dotted line represents an AUC of 0.5. The x-axis is the data set in which the model was

 initially trained on.
- Figure S5: Random Forest Prediction Success of Carcinoma Using Genera for each
 Tissue Study. A) AUC for prediction in unmatched tissue for all genera or CRC-associated
 genera only. B) AUC for prediction in matched tissue using all genera or CRC-associated
 genera only. The dotted line represents an AUC of 0.5. The x-axis is the data set in which
 the model was initially trained on.
- Figure S6: Random Forest Prediction Success of Adenoma Using Genera for each
 Tissue Study.
